

Topic 3: Error Detection and Recovery

General Error Detection System

- ⊕ Transmitter (encoder) **adds redundancy** to user **information** to become **codewords** and transmit codewords over communication channel
- ⊕ All transmitted codewords satisfy **certain pattern** that is agreed upon between transmitter and receiver
- ⊕ If a received codeword doesn't satisfy the pattern, it is in error
 - ➡ Error detected!

Example: Single Parity Check Code

- ⊕ Append an overall parity check bit to k information bits

Information Bits: $(b_{k-1}, \dots, b_1, b_0)$

Parity Check Bit: $b_k = (b_{k-1} + \dots + b_1 + b_0) \bmod 2$

Codeword: $(b_k, b_{k-1}, \dots, b_1, b_0)$

- ⊕ **Pattern: all codewords have even # of 1's**
- ⊕ Receiver checks whether # of 1's is even
 - ➡ All errors that change an odd number of bits are detectable
 - ➡ All even-numbered errors are undetectable
- ⊕ Parity check bit is used in ASCII characters

Error Vector

- ⊕ Suppose we transmit a codeword that has n bits
- ⊕ Define the error vector $\underline{e} = [e_{n-1}, \dots, e_1, e_0]$ where
 - ➡ $e_i = 1$ if error occurs to the i^{th} bit position
 - ➡ $e_i = 0$ otherwise
- ⊕ **Fraction of Undetectable Errors (FUE)**
 - ➡ $\text{FUE} = \text{total \# undetectable errors} / \text{total \# valid errors}$

Error Burst

⊕ Errors can be classified according to:

➡ Number of bit error positions: **M-bit error**

➡ Separation of bit error positions: **error burst of length L**

- Error starts at bit position i and ends at bit position $(i + L - 1)$
